TP2 Risk Management

TP2: Hair Parra, Alessio Bressan, Ioan Catalin

2023-04-10

Libraries

Risk Management: European Options Portfolio

The objective is to implement (part of) the risk management framework for estimating the risk of a book of European call options by taking into account the risk drivers such as underlying and implied volatility.

Data

.. ..\$: NULL

.. ..\$: chr [1:3] "K" "tau" "IV"

##

Load the database Market. Identify the price of the **SP500**, the **VIX index**, the term structure of interest rates (current and past), and the traded options (calls and puts).

```
# load dataset into environment
load(file = here("data raw", "Market.rda"))
# reassign name and inspect structure of loaded data
mkt <- Market
summary(mkt)

```

plot(sp500)
plot(vix)

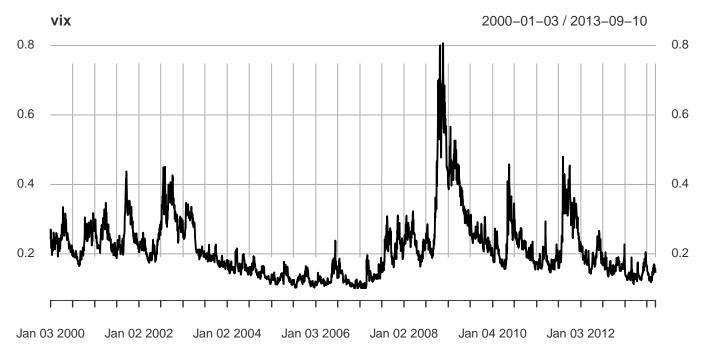

Let's unpack these into the env. individually:

```
# unpack each of the elements in the mkt list
sp500 <- mkt$sp500
vix <- mkt$vix
Rf <- mkt$rf # risk-free rates
calls <- mkt$calls
puts <- mkt$puts

# assign colname for aesthetic
colnames(sp500) <- "sp500"
colnames(vix) <- "vix"</pre>
```

```
SP500 and VIX
By inspection, we observe that we the SP500 and VIX indices are contained in the sp500 and vix xts objects respectively.
# show head of both indexes
head(sp500)
##

Pricing a Portfolio of Options

Black-Scholes

Notation:

- S_t = Current value of underlying asset price
- K = Options strike price
- T = Option maturity (in years)
- t =time in years
- $\tau = T t =$ Time to maturity
- r =Risk-free rate
- y Dividend yield
- R = r y
- $\sigma =$ Implied volatility
- c =Price Call Option
- p = Price Put Option

Proposition 1 (Black-Scholes Model). Assume the notation before, and let $N(\cdot)$ be the cumulative standard normal distribution function. Under certain assumptions, the Black-Scholes models prices Call and Put options as follows:

$$\begin{cases} C(S_t, t) = Se^{yT}N(d_1) - Ke^{-r \times \tau}N(d_2), \\ \\ P(S_t, t) = Ke^{-r \times \tau}(1 - N(d_2)) - Se^{y \times T}(1 - N(d_1)), \end{cases}$$

where:

$$\begin{cases} d_1 = \frac{\ln\left(\frac{S_t}{K}\right) + \tau\left(r + \frac{\sigma^2}{2}\right)}{\sigma\sqrt{\tau}} \\ d_2 = d_1 - \sigma\sqrt{\tau} \end{cases}$$

, further the Put Option price corresponds to the **Put-Call parity**, given by:

$$C(S_t, t) + Ke^{-r \times \tau} = P(S_t, t) + S_t$$

Note As here we don't have dividends, then y = 0, and so

$$\begin{cases} C(S_t, t) = S_t N(d_1) - K e^{-r \times \tau} N(d_2), \\ \\ P(S_t, t) = K e^{-r \times \tau} (1 - N(d_2)) - S_t (1 - N(d_1)), \end{cases}$$

Implementation

```
get_d1 <- function(S_t, K, tau, r, sigma){
    ### Compute d1 for the Black-Scholes model
    # INPUTS

# S_t: Current value of underlying asset price

# K: Strike Price

# tau: T- t, where T=maturity, and t=current time

# r: risk-free rate

# sigma Implied volatility (i.e. sigma)

num <- (log(S_t/K) - tau*(r + 0.5*sigma**2)) # numerator
denom <- sigma * sqrt(tau) # denominator

return(num/denom)</pre>
```

```
}
get_d2 <- function(d1, sigma, tau){</pre>
  ### Compute d2 for the Black-Scholes model
  # INPUTS
      d1: d1 factor calculated by the get_d1 function
      tau: T- t, where T=maturity, and t=current time
      sigma Implied volatility (i.e. sigma)
 return(d1 - sigma * sqrt(tau))
}
# Function to implement the Black-Scholes model
black_scholes <- function(S_t, K, r, tau, sigma, put=FALSE){</pre>
  # Calculates a Call (or Option) price using Black-Scholes
  # INPUTS
      S_{-}t:
                [numeric] Current value of underlying asset price
      K:
               [numeric] Strike Price
               [numeric] risk-free rate
      r:
      tau:
  #
               [numeric] T- t, where T=maturity, and t=current time

Book of Options

Assume the following book of **European Call Options:**

```
1. 1x strike K = 1600 with maturity T = 20d
2. 1x strike K = 1605 with maturity T = 40d
```

3. **1x** strike K = 1800 with maturity T = 40d

Find the price of this book given the last underlying price and the last implied volatility (take the VIX for all options). Use Black-Scholes to price the options. Take the current term structure and linearly interpolate to find the corresponding rates. Use 360 days/year for the term structure and 250 days/year for the maturity of the options.

Nearest values

This function will obtain the two nearest values a, b for a number x in a vector v, such that a < x < b.

```
# Obtain the two nearest values of x in vec.
get_nearest<- function(x, vec){</pre>
  # find all the numbers that are bigger and smaller than x in vec
  bigger <- vec >= x
  smaller <- vec <= x</pre>
  # filter only values with TRUE
  bigger <- bigger[bigger == TRUE]</pre>
  smaller <- smaller[smaller == TRUE]</pre>
  # obtain the indexes for the left and upper bound
  a_idx <- length(smaller)</pre>
  b_idx <- length(smaller)+1</pre>
  # retrieve values from original vector
  a <- vec[a idx]
  b <- vec[b_idx]</pre>
  # return the retrieved values
  return(c(a,b))
}
# Test
days <- rf_mat[, "days"]</pre>
get_nearest(40, rf_mat[, "days"]) # nearest day values
## 1m 3m
## 30 90
```

Linear Interpolation

Given two known values (x_1, y_1) and (x_2, y_2) , we can estimate the y-value for some x-value with:

$$y = y_1 + \frac{(x - x_1)(y_2 - y_1)}{(x_2 - x_1)}$$

```
# Function to interpolate y given two points
interpolate <- function(x,x1=1,y1=1,x2=2,y2=2){
  y1 + (x-x1)*(y2-y1)/(x2-x1)
}</pre>
```

Finding the rates through interpolation

The **yield curve** for the given structure of interest rates can be modeled a function $r_f = f(x)$, where x is the number of years. Then, we can interapolate the values as follows:

```
# Interest rates
rf_mat
```

```

Next, using the function above we price the book of options given:

```
1. 1\mathbf{x} strike K = 1600 with maturity T = 20d
2. 1\mathbf{x} strike K = 1605 with maturity T = 40d
3. 1\mathbf{x} strike K = 1800 with maturity T = 40d
```

First, we retrieve the latest value for the underlying (SP500) and the latest implied volatility (VIX):

```
S_t = sp500[length(sp500)] # last price of underlying
IV = vix[length(vix)] # last volatility
```

Then, we price the options accordingly:

```
# First Call Option
price_option(T=20, K=1600, calls=calls, rf_mat=rf_mat, S_t = S_t, IV = IV)

Two risk drivers and copula-marginal model (Student-t and Gaussian Copula)

- 1. Compute the daily log-returns of the underlying stock
- 2. Assume the first invariant is generated using a Student-t distribution with $\nu = 10$ df and the second invariant is generated using a Student-t distribution with $\nu = 5$ df.
- 3. Assume the **normal copula** to merge the marginals.
- 4. Generate 10000 scenarios for the one-week ahead price for the underlying and the one-week ahead VIX value using the copula.
- 5. Determine the P&L distribution of the book of options, using the simulated values.
- 6. Take interpolated rates for the term structure.

Gaussian Copula with two Student-t marginals

A bivariate distribution H can be formed via a copula C from two marginal distributions with CDFs F and G via:

$$H(x,y) = C(F(x), G(y)) = C(F^{-1}(u), G^{-1}(u))$$

with density

$$h(x,y) = c(F(x), G(y))f(x)g(y)$$

The **Gaussian Copula** is given by:

$$C_{\rho}^{\text{Gauss}}(u,v) = \Phi_{\rho}(\Phi^{-1}(u), \Phi^{-1}(v)).$$

In this case, a Gaussian copula with two Student-t marginals with CDFs $t(\nu_1)$ with ν_1 degrees of freedom and $t(\nu_2)$ with ν_2 degrees of freedom is given by:

$$C_{\rho}^{\mathrm{Gauss}}(u,v) = \Phi_{\rho}(F_{\nu_1}^{-1}(u), F_{\nu_1}^{-1}(v)),$$

where F_{ν_1} and F_{ν_2} are their respective CDFs.

Log-returns

The **discrete returns** are given by:

$$R_{t+1} = \frac{P_{t+1} - P_t}{P_t}$$

and the next ahead log-returns are given by:

$$\log(R_{t+1}) = \log(P_{t+1} - P_t) - \log(P_t)$$

```

Computing Prices from Returns

Next, we crate a function to forecast the 5 day ahead prices from the returns. Since:

$$R_t = \frac{P_t - P_{t-1}}{P_{t-1}}$$

$$\implies R_t = \frac{P_t}{P_{t-1}} - 1$$

$$\implies \log(R_t) = \log\left(\frac{P_t}{P_{t-1}}\right)$$

$$\implies \log(R_t) = \log(P_t) - \log(P_{t-1})$$

$$\implies \log(P_t) = \log(R_t) + \log(P_{t-1})$$

$$\implies P_t = \exp(\log(R_t) + \log(P_{t-1}))$$

$$\implies P_{t+1} = \exp(\log(R_{t+1}) + \log(P_t))$$

Since:

$$\exp\log(R_t) + \log(P_{t-1}) = \log(R_t \cdot P_{t-1})$$

```
# Obtain Initial values (last value of simulation)
spT <- sp500[length(sp500)][[1]]</pre>
vixT <- vix[length(vix)][[1]]</pre>
# Initialize empty matrices for the simulated sp500 and vix values
sim_val_mats <- initialize_sim_mats(sim_rets_sp500,</pre>
                                          lnames = c("sp500", "vix"), # <- this function comes from Utils.R</pre>

Pricing the simulation scenarios

Recall the initial (call) options:

```
1. \mathbf{1x} strike K = 1600 with maturity T = 20d
2. \mathbf{1x} strike K = 1605 with maturity T = 40d
3. \mathbf{1x} strike K = 1800 with maturity T = 40d
```

Option Pricing of Simulated Values

Next, we calculate the price of the book of options for the simulated values.

```
# random seed for replication
set.seed(123)
# Initialize empty matrices to store the simulated option prices (aka premiums)
opt_price_mats <- initialize_sim_mats(sim_price_sp500,
                                        lnames = c("opt1", "opt2", "opt3"),
                                        num mats = 3
                                        )
# maturities for each of the options
T1 <- 20

Distribution of the Profit and Loss for the Book Of Options

Recall the profit functions for European options:

Parameters

Parameters: - S: Spot price (current) - S_0 : Spot price at the beginnin of the option - S_T : Spot price at maturity - T: Maturity of option - K: Strike price - c: Price of Call option - p: Price of Put option

Profit at Maturity

The profit functions of a long call and a long put are given by:

$$\pi^{\text{Long Call}} = \max(S_T - K, 0) - c$$
$$\pi^{\text{Long Put}} = \max(K - S_T, 0) - p$$

Calculating the profits

For each of the simulated prices and resulting premiums, we want to calculate the profit generated at each simulation timestep:

```
# Matrices of profit and loss for each of the options simulations
PL_mats <- initialize_sim_mats(sim_price_sp500,
                                        lnames = c("PL1", "PL2", "PL3"),
                                        num mats = 3
                                        )
# Calculate profit for all simulated options at each day ahead
for(t in 1:n_ahead){
  #spot price of underlying at day T+t
  spot <- sim_price_sp500[, t]</pre>
  # Option profit for K1 at time T+t with premiums c1
  c1 <- opt_price_mats$opt1[, t] # extract the premiums</pre>
  PL_mats$PL1[,t] <- option_profit(S=spot, K=K1, c=c1)$call_profit
  # Option profit for K1 at time T+t with premiums c1
  c2 <- opt_price_mats$opt2[, t] # extract the premiums</pre>
  PL_mats$PL2[,t] <- option_profit(S=spot, K=K2, c=c2)$call_profit
  # Option profit for K1 at time T+t with premiums c1
```

```
c3 <- opt_price_mats$opt3[, t] # extract the premiums</pre>
  PL_mats$PL3[,t] <- option_profit(S=spot, K=K2, c=c3)$call_profit
}
# display profit matrices
head(PL_mats$PL1)

Distribution of Options P/L

Next, using all the simulated profits and losses for each of the options, we display a histogram for the distribution for each of the options, for the aggregated 5 days of simulation:

```
# flatten the matrices 5-days ahead simulated P/L for the three options
sim_pl_opt1 <- as.vector(PL_mats$PL1)
sim_pl_opt2 <- as.vector(PL_mats$PL2)
sim_pl_opt3 <- as.vector(PL_mats$PL3)

# Compute the 95% VaR and 95% ES
opt1_VaR_ES <- f_VaR_ES(sim_pl_opt1, alpha = 0.05)
opt2_VaR_ES <- f_VaR_ES(sim_pl_opt2, alpha = 0.05)
opt3_VaR_ES <- f_VaR_ES(sim_pl_opt3, alpha = 0.05)

# plot the distribution for each of the options
par(mfrow = c(2,2))
hist(sim_pl_opt1, nclass = round(10 * log(n_sim)), probability = TRUE)
lines(density(sim_pl_opt1), lwd=2, col="blue")
abline(v=opt1_VaR_ES$VaR, col="red") # 95% VaR
abline(v=opt1_VaR_ES$ES, col="black") # expected shortfall
rug(sim_pl_opt1)</pre>
```

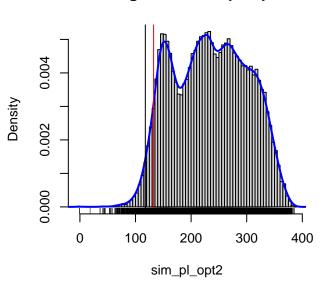

```
hist(sim_pl_opt2, nclass = round(10 * log(n_sim)), probability = TRUE)
lines(density(sim_pl_opt2), lwd=2, col="blue")
abline(v=opt2_VaR_ES$VaR, col="red") # 95% VaR
abline(v=opt2_VaR_ES$ES, col="black") # expected shortfall
rug(sim_pl_opt2)

hist(sim_pl_opt3, nclass = round(10 * log(n_sim)), probability = TRUE)
lines(density(sim_pl_opt3), lwd=2, col="blue")
abline(v=opt3_VaR_ES$VaR, col="red") # 95% VaR
abline(v=opt3_VaR_ES$ES, col="black") # expected shortfall
rug(sim_pl_opt3)
```

VaR95

Definition

For a random variable X, the Value-at-Risk (VaR) at level α is defined as the α -lower quantile of the distribution of X, thus:

$$VaR_X(\alpha) = F_X^{-1}(1-\alpha)$$

First Option

```
opt1_VaR_ES$VaR # first option

## [1] 137.2302

opt2_VaR_ES$VaR # second doption

## [1] 132.5263

opt3_VaR_ES$VaR # third option
```

[1] 230.0578

ES95

Expected shortfall is calculated by averaging all of the returns in the distribution that are worse than the VAR of the portfolio at a given level of confidence.

display opt1_VaR_ES\$ES

[1] 121.0392

opt2_VaR_ES\$ES

[1] 117.6614

opt3_VaR_ES\$ES
